Implementation of a neural network for poker behavior classification

Andrea Mazzei

Fast, introductory frame.

Aim of this work is to generate a pattern recognition tool to distinguish winning regular poker players from losing ones.

The initial idea was to include regularly losing players in the analysis (in jargon called fishes), but due to the absence of a valid dataset, this idea have been abandoned.

This work is roughly divided in three sections:

- Data Mining

- Definition of the problem

- Output analysis

Data entry

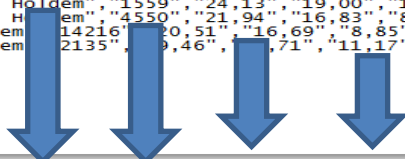

11/26/15

Passing data to matlab.

All data is gathered from my personal poker account and is recorded by the third party software Hold'em Manager 2 (HM). HM is able to save players' reports in .csv files. Each report must be saved manually.

In order to adapt to the input structure requested by the pattern recognition tools provided by matlab, a bit of data manipulation has been implemented

BIG data?

Fishy opponents play less! A possibility would be to gather all of em into an alias

BIG data?

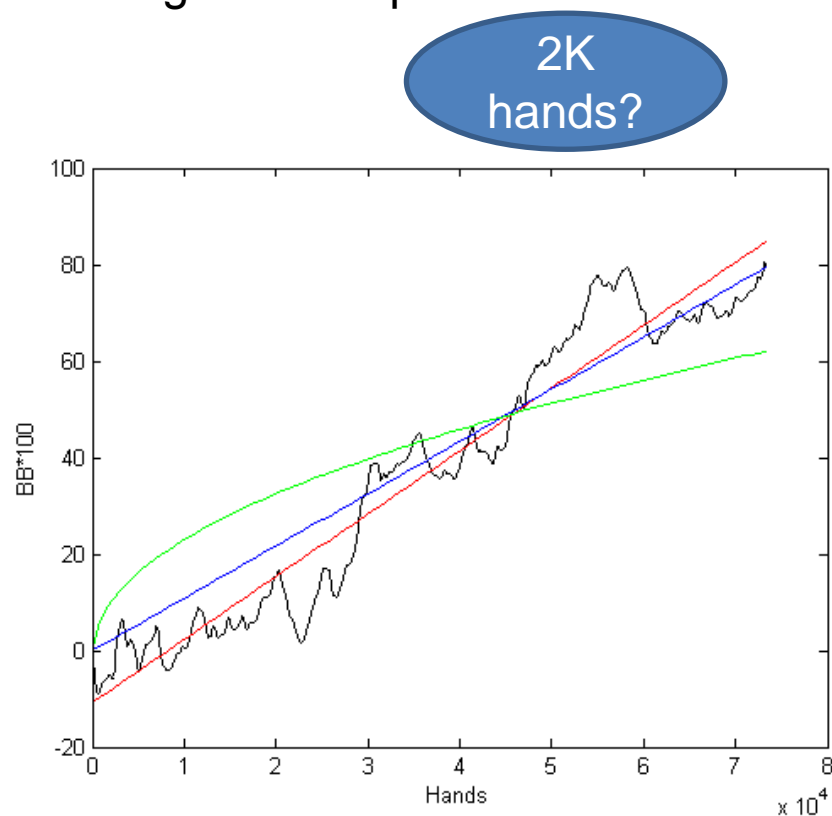

Fishy opponents play less! A possibility would be to gather all of em into an alias

Correct definition of “BIG”

Online poker is essentially aleatoric. By examining the stochastic process associated to hero's personal hands, we can infer information on the variance of the process. Our aim is now to define what is a “good” sample.

Data entry

11/26/15

The mining rate

Input data (“features”): The list of sensible stats available for the players. Those range from very common stats to very improbable one (as example “Missed cbet turn after check raising flop on 3bet pot”, completely useless unless we got a good sample. It should range around 100K hands on that opponent).

Some stats are easy to mine (VIP and PFR take 1 hand per sample), while some others are gathered much more slowly (some actions are “rare” events and also depend on the possibility of committing that action).

Input data (“target”): The oracle for the network, seems pretty legit to consider their winrate (\$/hand, more properly expressed in bb/100hands) as a good oracle... however some precautions must be taken

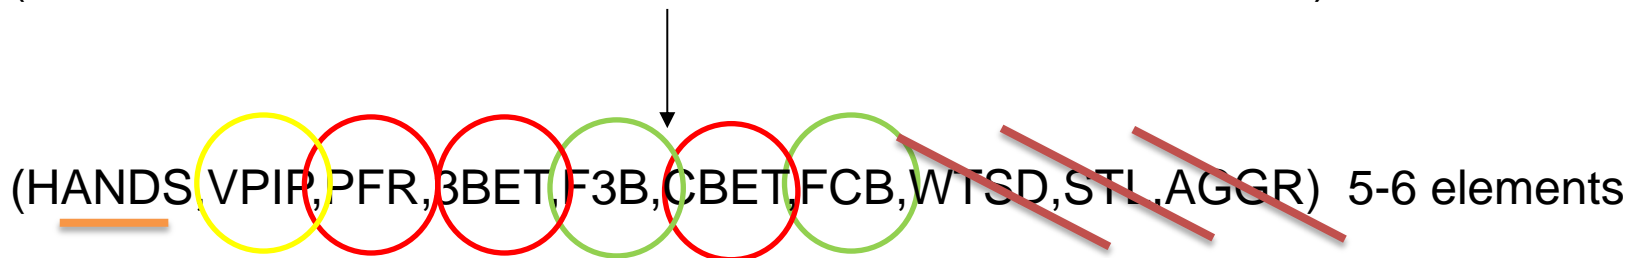

The features vector

(HANDS,VPIP,PFR,3BET,CCL,CBET,FCB,WTSD,STL,AGGR) 10 elements

The features vector

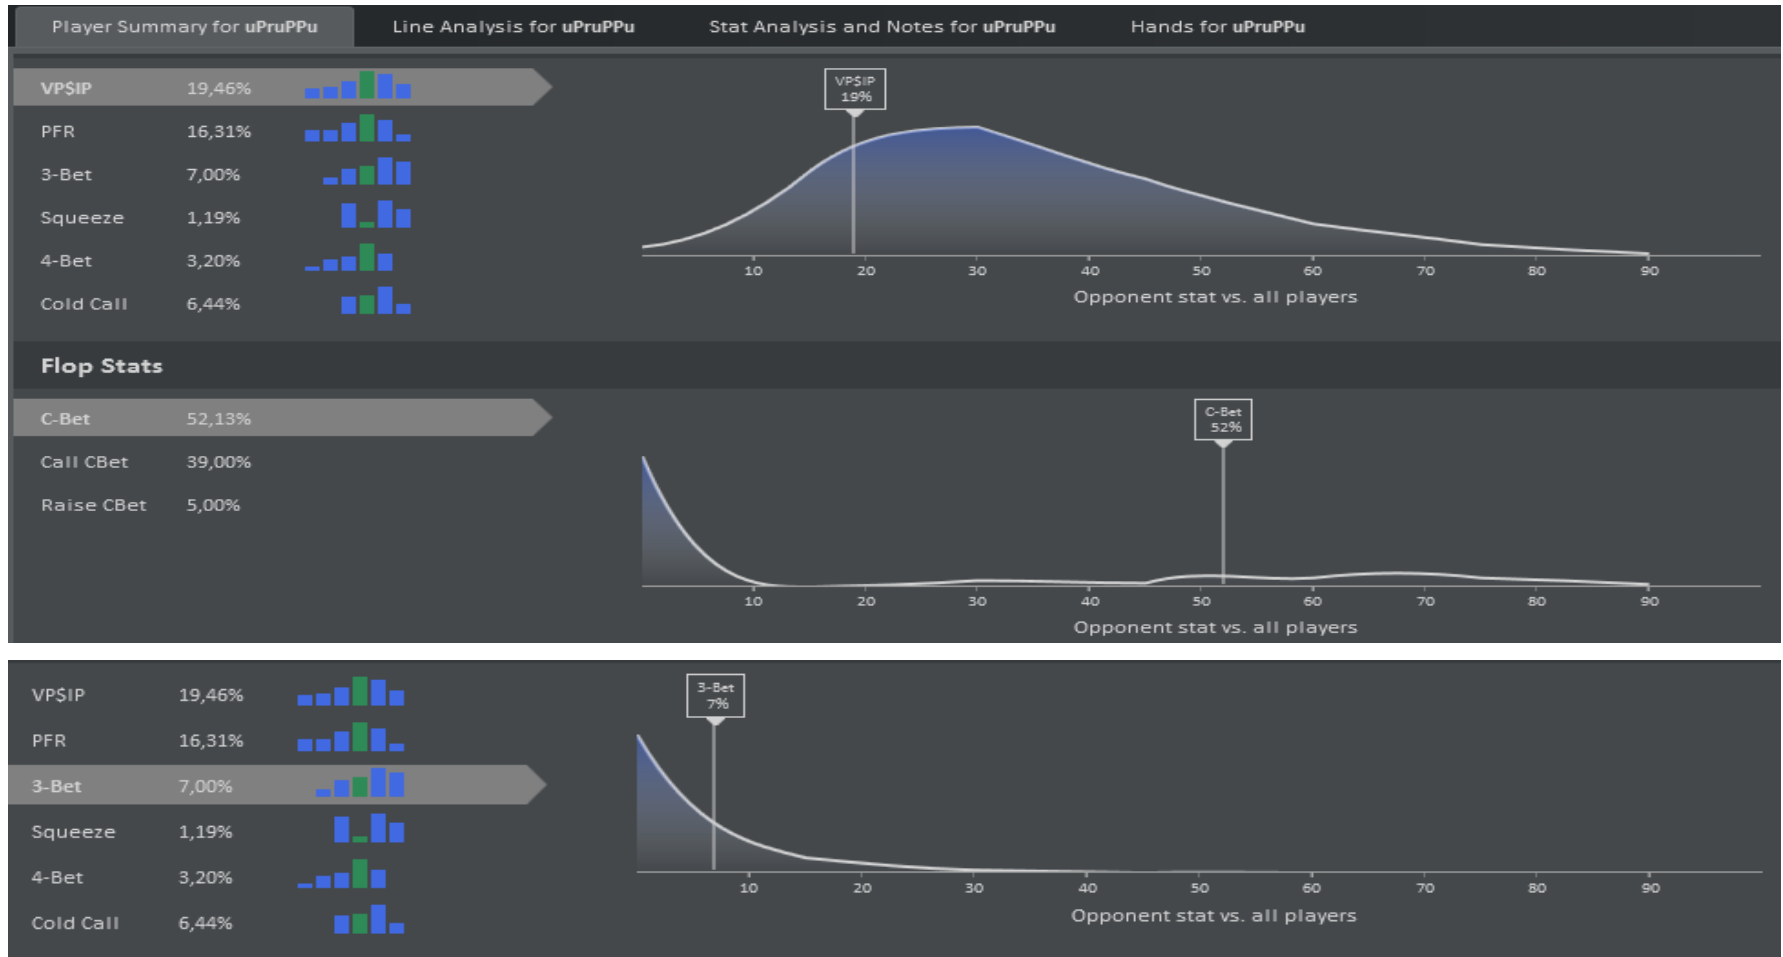

(HANDS,VPIP,PFR,3BET,CCL,CBET,FCB,WTSD,STL,AGGR) 10 elements

(HANDS,VPIP,PFR,3BET,F3B,CBET,FCB,WTSD,STL,AGGR) 5-6 elements

The diagram illustrates the selection of features from a 10-element vector. The top row shows the full set of features: (HANDS,VPIP,PFR,3BET,CCL,CBET,FCB,WTSD,STL,AGGR). An arrow points from the 'CCL' feature to the 'F3B' feature in the bottom row. The bottom row shows a reduced set of features: (HANDS,VPIP,PFR,3BET,F3B,CBET,FCB,WTSD,STL,AGGR). The features are highlighted with colored circles: HANDS (orange underline), VPIP (yellow circle), PFR (red circle), 3BET (red circle), F3B (green circle), CBET (red circle), FCB (green circle), WTSD (red diagonal line), STL (red diagonal line), and AGGR (red diagonal line). The bottom row is labeled '5-6 elements'.

Poker player experience comes handy here.

Discriminatory power (qualitatively)

The oracle?

Intuition suggest that the correct question for determining a good player is:

Is he winning money? (or, better, is his bb/100 positive?)

Since the response suffers of indetermination, a good player might has been recorded as non-winning. A way to overcome is to consider the so-called all-inEV adjusted winrate.

-330 bb at the end of the game session? Bad player or bad classification?

All-in EV winnings
VS
Net winnings

Improving the oracle.

Target

11/26/15

Improving the oracle.

Net Won is -116bb

Adj. Won is $-116bb \cdot 0.17 + 109bb \cdot 0.83 = 71bb$

In this way we are able to remove, at least partially,
the aleatoric character of the target set.

Target

11/26/15

Improving the oracle.

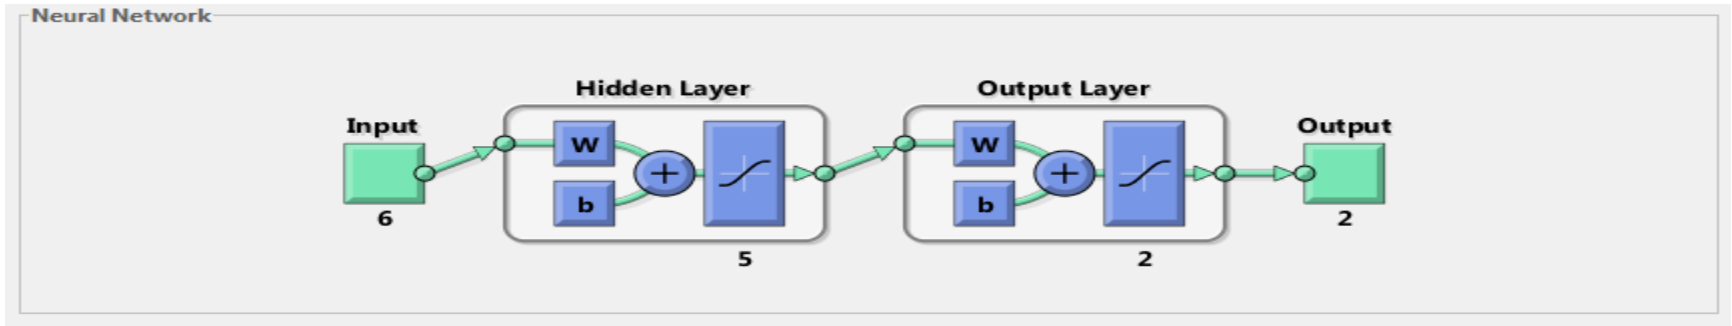

Moreover, player with small game samples may have been recorded in a surprisingly lucky or unlucky session (variance rush). In order to balance this behaviour, players at the tails of the bb100 distribution have been cut out.

Target

11/26/15

The neural network toolbox

Properties of the network:

#layers: 1 + 1 hidden.

Acceptance function: sigmoid.

Output: binary (two classes).

Method: gradient descent.

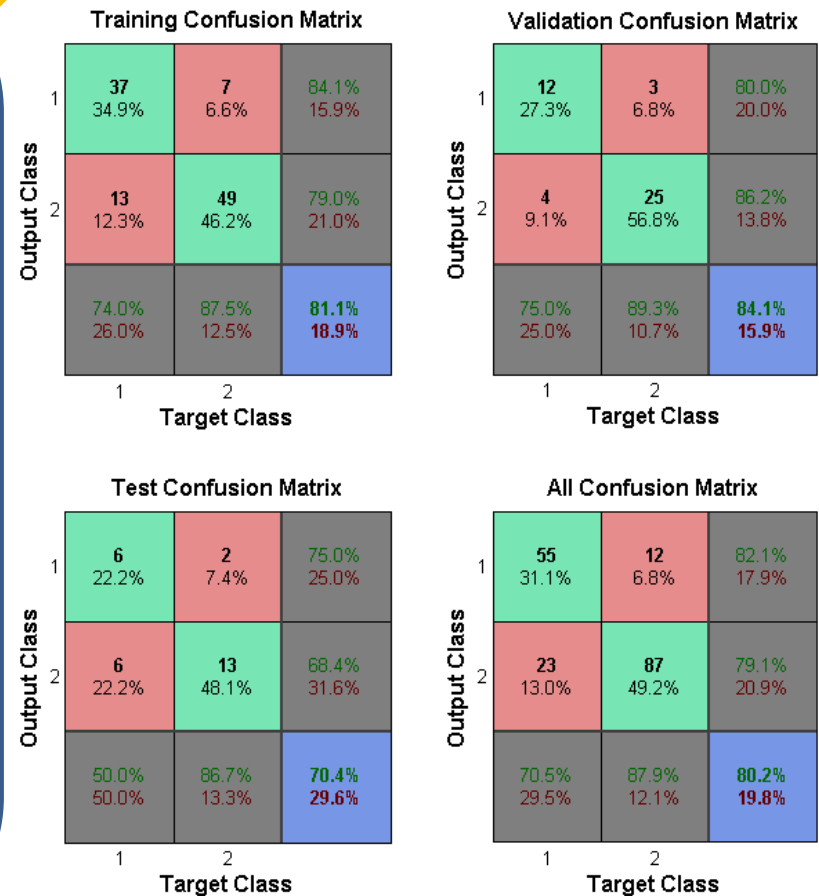

Training of the network

Data is composed of 200 different reports, with a cutoff at 1000 hands. If the number of hands in the report is lesser than the cutoff, the report is ignored. If we lower the hand-cutoff we get more data for the training, but we increment the error associated to the oracle.

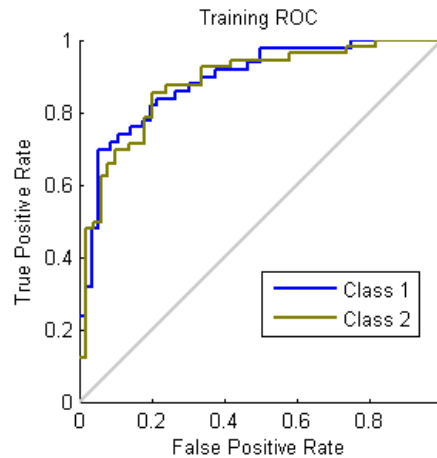

The toolbox suggests a partitioning for the training, validation and testing elements of 70%, 15%, 15%. Unfortunately, these values restrict our count to only a few element for the latter two phases. I prefer a slightly higher sample for the validation partition, around 25%.

The number of neurons has been varied manually in a range from two to ten. The majority of the runs have been made with a value of four and five neurons.

Output of the network.

Output of the network.

Error distribution is still large

Interpreting the output.

Colormap for the hidden layer weights. It is possible to read some informations here.

As expected, FCB and PFR value are strong indicators of the presence of Category 2 player, whilst the 3BET stat and CBET stat are strong indicators of the opposite.

Non linearly-separable?

The Continuation bet example:

Poker theory suggests to cbet as frequently as possible, combined to the evaluation on how much our opponent is likely to fold. On low stakes cash games, due to the vastity of fishes in the field with a low fold to cbet value, cbet optimal ranges have a net lower and upper bound.

Considerations and conclusions.

- 1) Some basic poker theory elements confirmed.
- 2) Some others not completely.
- 3) Absence of big data, should more data improve?
- 4) The output is almost completely arbitrary if net won assumed as target.
- 5) Drastic improvements when considering equity.
- 6) Next step will be automation of the data mining process.
- 7) Task is to create a useful tool for players.
